

# Cell reproduction and cycle

- How cells replace or “clone” themselves

Because DNA stores genetic information and is faithfully replicated, information is passed largely unaltered from cell-to-cell, generation-to-generation.

2014, MIT/RRE/EGR/AB, SITH ITB

## Eukaryotic cells divide in one of two ways

In eukaryotes, nuclei divide by either: mitosis or meiosis.

### mitosis

- Occurs in somatic (nonreproductive) cells
- Asexual reproduction, development, growth and cell replacement are mitotic divisions

### meiosis

- Occurs in germ (reproductive) cells
- Results in the production of gametes

2014, MIT/RRE/EGR/AB, SITH ITB

## The Knot of Identity - Mitosis Precisely and Evenly Divides Duplicated Chromosomes

Precisely dividing the duplicated chromosomes has the consequence of providing each new cell with an identical and complete set of genetic instructions.

2014, MIT/RRE/EGR/AB,SITH ITB

## Mitosis Precisely and Evenly Divides Duplicated Chromosomes

Cytokinesis is the process of cell division and it is distinct and separable from mitosis. Cell division is necessary for reproduction, growth, and repair of an organism.

2014, MIT/RRE/EGR/AB,SITH ITB

## Death and division: a balancing act

## Cell cycle

- The most basic function of the cell cycle is to **duplicate** accurately the vast amount of DNA in the chromosomes and then **segregate** the copies precisely into two genetically identical daughter cells.
- The eucaryotic cell cycle is divided into four sequential phases:  $G_1$ , **S**,  $G_2$ , and **M**.
- During most of the cell cycle, the cell is in interphase, which is divided into three subphases : S,  $G_1$ , and  $G_2$ .
- two major phases** of the cell cycle: S and M
  - DNA duplication occurs during S phase** (S for synthesis)  $\rightarrow$  10–12 hours (about half of the cell-cycle time in a typical mammalian cell).
  - After S phase, **chromosome segregation and cell division occur in M phase** (M for mitosis)  $\rightarrow$  less time (less than an hour in a mammalian cell). M phase involves a series of dramatic events that begin with nuclear division, or mitosis.

# Chromosome during cell cycle

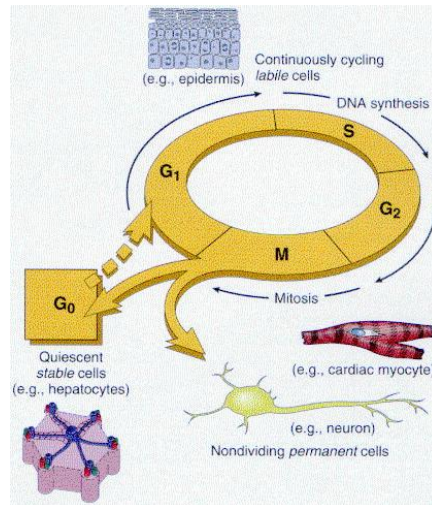

- Most cells require much more time to grow and double their mass of proteins and organelles than they require to replicate their DNA and divide.
- More time for growth → extra *gap phases* are inserted in cell cycles → a **G<sub>1</sub> phase** between M phase and S phase → a **G<sub>2</sub> phase** between S phase and mitosis.

2014, MIT/RRE/EGR/AB,SITH ITB

## The factors that promote organ or organism growth can be operationally divided into three major classes:

1. **Mitogens**  
stimulate cell division, primarily by relieving intracellular negative controls that otherwise block progress through the cell cycle.
2. **Growth factors**  
stimulate cell growth (an increase in cell mass) by promoting the synthesis of proteins and other macromolecules and by inhibiting their degradation.
3. **Survival factors**,  
promote cell survival by suppressing apoptosis.

2014, MIT/RRE/EGR/AB,SITH ITB

## Regulation of Cell Cycle

- Check points or switches control the rate of the cell cycle
- Intracellular and extracellular control
- G<sub>0</sub> state is the resting state
- G<sub>1</sub> checkpoint or the start checkpoint is said to be the beginning of the cell cycle.

**An overview of the cell-cycle control system.** The core of the cell-cycle control system consists of a series of cyclin-Cdk complexes (*yellow*). The activity of each complex is also influenced by various inhibitory checkpoint mechanisms, which provide information about the extracellular environment, cell damage, and incomplete cell-cycle events (*top*). These mechanisms are not present in all cell types; many are missing in early embryonic cell cycles.

2014, MIT/RRE/EGR/AB,SITH ITB

### ACTIVATION OF CELL CYCLE CHECKPOINT ?

2014, MIT/RRE/EGR/AB,SITH ITB

# Cyclin and CDK

- Cyclin binds to Cdk
- CDK (cyclin dependent kinases)
  - Protein Kinases → enzymes that transfer a phosphate group from ATP to a target protein
  - These Kinases are regulated by cyclins
- Cyclin Cdk complexes regulate the passage of cells from G1 into S phase and from G2 into M phase.

EERO MÄNTYRANTA won two Olympic gold medals in 1964. Years later scientists found the source of the Finnish cross-country skier's endurance. A genetic mutation gave his family higher than normal levels of oxygen-carrying red blood cells—higher even than could be achieved with EPO.

**Myostatin** acts by inhibiting the growth of muscles. It prevents muscles from growing too large i.e. **inhibits proliferation of myoblasts** that fuse to form skeletal muscle cells.

- Mutation in myostatin → proliferation & growth >>>
- Inactivated myostatin → German Superboy

## PUMPING UP WITH GENES

Building athletes' muscle, tweaking its composition, and boosting endurance are enhancements theoretically possible with gene therapy. Using a synthetic gene to simulate an injury signal spurs repair activity by stem cells (right), leaving muscle fibers bigger and stronger. Activating a dormant gene or adding a new one could change muscle fiber types (below). Unlike systemic drugs, gene therapy also allows key muscle subgroups to be targeted based on the biomechanics of a given sport.

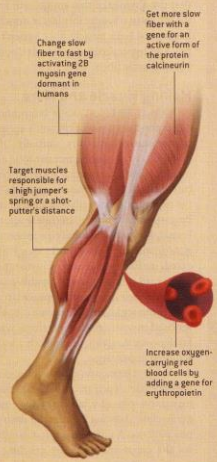

**1** Nuclei  
Muscle fiber

**2** Satellite cell

**3** Fiber cross section

**IN NORMAL MUSCLE**, a fiber's multiple nuclei (1) are responsible for driving the manufacture of new proteins. When repair is needed, chemical signals from the wound draw satellite cells, which proliferate before fusing with the fiber to contribute their nuclei to the effort (2). The addition of more nuclei and fresh myofibrils leaves a repaired fiber bulkier than before it was injured (3).

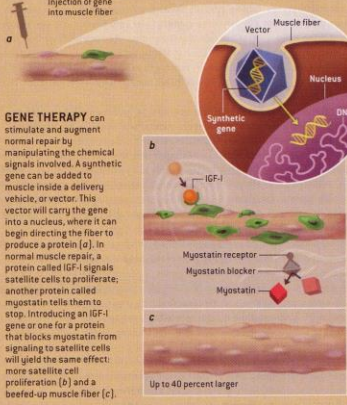

Change slow fiber to fast by activating 28 myosin gene dormant in humans

Get more slow fiber with a gene for an active form of the protein calcineurin

Target muscles responsible for a high jumper's spring or a shot-putter's distance

Increase oxygen-carrying red blood cells by adding a gene for erythropoietin

**GENE THERAPY** can stimulate and augment normal repair by manipulating the chemical signals involved. A synthetic gene can be added to muscle inside a delivery vehicle, or vector. This vector will carry the gene into a nucleus, where it can begin directing the fiber to produce a protein ( $\alpha$ ). In normal muscle repair, a protein called IGF-1 signals satellite cells to proliferate; another protein called myostatin tells them to stop. Introducing an IGF-1 gene or one for a protein that blocks myostatin from signaling to satellite cells will yield the same effect: more satellite cell proliferation (b) and a beefed-up muscle fiber (c).
